

Factors Affecting the Setting Time and Compressive Strength of Alkali Activated Ground Granulated Blast Furnace Slag Reinforced with Wollastonite

Valeria A. Gonzalez, Benjamin Varela, Joseph Voelkel

Abstract—We conducted a Design of Experiments to analyze and optimize the effect of the $\text{SiO}_2/\text{K}_2\text{O}$, $\text{H}_2\text{O}/\text{K}_2\text{O}$ molar ratios of a Potassium base activating solution, slag/solution, Wollastonite/Slag mass ratios and mixing amount in the compressive strength and setting time of alkali activated Ground granulated Blast Furnace Slag. It was found that the total amount mixed had little to no effect in the compressive strength and the setting time. The setting time was largely affected by the slag/solution mass ratio followed by the $\text{SiO}_2/\text{K}_2\text{O}$ molar ratio in the activating solution. For the compressive strength the largest correlation was found in the joint effect of the slag/solution and Wollastonite/slag mass ratios. The optimum formulation had seventh day compressive strength of 8000 Psi (55 Mpa) and setting time of 36 minutes was found when the activating solution had molar ratios of $\text{SiO}_2/\text{K}_2\text{O} = 1$, $\text{H}_2\text{O}/\text{K}_2\text{O} = 10$ and mass ratios of slag/solution = 1.75 and Wollastonite/Slag=0.37.

I. INTRODUCTION

The beneficial use of solid industrial wastes has found a niche application in the construction and cement industries. There are many benefits resulting from the reuse of these wastes, especially in the production of ordinary Portland cement. Portland cement is of critical importance for the construction industry of the nation. In 2011, approximately 66 million metric tons of cement were produced in the United States, worth approximately 6.6 billion dollars (van Oss 2012). Despite its importance, Portland cement production has a negative environmental impact. The production of one ton of cement is energy intensive, releases approximately one ton of CO_2 and uses large quantities of virgin raw material (Harditjo & Rangan 2005). For this reason Ground Granulated Blast Furnace Slag (GGBFS), among other industrial wastes, has been used to partially replace the amount of clinker in the production of Portland cement (EPA 2009). The substitution of virgin raw materials by less expensive industrial wastes saves energy, reduces construction costs and in some cases it yields concretes with enhanced mechanical properties.

Alkali-activated binders present similar or better mechanical properties than those based on Portland cement. This higher performance has led to extensive research on the topic showing significant conclusions on the economic and environmental benefits of using this material in the construction industry. Previous research shows that alkali-activated binders develop a high early compressive strength, lower hydration heat, better resistance to chemical attack, better behavior upon carbonation, higher resistance of the aggregate matrix interface, better behavior to freeze-thaw cycles, among others (Wang, Pu & Scrivener 1995; Tailing & Brandster 1989). Additionally these binders also exhibit rapid setting times, high shrinkage resulting in micro-cracks, and in some cases higher formation of salt efflorescence (Puertas 1995).

GGBFS is a by-product from the iron and steel manufacturing industry. It is produced through the rapid cooling of the molten slag that floats on top of the molten iron in the furnace. The rapid cooling is induced by immersion in water and results in a glassy, granular product that is then dried and ground into fine powder. Its chemical composition includes SiO_2 , CaO , MgO and Al_2O_3 , with small traces of Fe_2O_3 , K_2O and Na_2O . Its chemical composition, amorphous nature and fineness allows GGBFS to react with alkaline solutions producing a cementitious material.

Activators based on sodium hydroxide, sodium silicate and sodium sulfate have been widely used to activate GGBFS. Published results suggest that activators composed of a mixture of sodium silicate and sodium hydroxide yield mortars with higher compressive strengths (Fernandez-Jimenez, Palomo & Puertas 1999). However, empirical observations show that sodium based activators are more prone to efflorescence than activators based on potassium solutions. Efflorescence not only produces an undesirable look in the samples but also tends to decrease their strength. Wollastonite is a crystalline calcium metasilicate (CaSiO_3) mineral which occurs in metamorphosed siliceous limestones, and in alkaline igneous rocks. Wollastonite rocks are grounded and impurities such as garnet removed by high intensity magnetic separators. This process yields mineral microfibers with an acicular shape, an average size of $40\mu\text{m}$ and aspect ratio of 15:1, although these dimensions can vary depending on the processing. Some of the interesting physical properties of Wollastonite include high melting temperature (1410°C), low coefficient of thermal expansion ($6.5 \times 10^{-6} \text{ mm/mm}^\circ\text{C}$) and hardness of 4.5 in the Mohs scale (Nycos 2012). The combination of physical properties and morphology make Wollastonite microfibers an important

material in applications where enhanced durability and strength are required. Wollastonite microfibers have proved to increase compressive and tensile strengths, reduced shrinkage and crazing, increase durability during freeze-thaw cycles in concrete formulations and improve the fracture toughness in alkali activated pastes (Silva 7 Thaumaturgo 2002).

The capacity of ground granulated blast furnace slag (GGBFS) to react with an alkali solution forming a material with properties comparable to Portland cement was first reported by A.O. Purdon (1940). During the 1950's, due to cement shortages in the former Soviet Union, extensive research to develop alternative binders using metallurgical slags was conducted by V.D. Glukhovskiy, who named these binders as "soil cements". However much of this work was unknown in the West until recent years. P. Krivenko, who continued this research in Ukraine, named this binders "geocements" due to the similarities between the characteristics of these products and those of some natural minerals. Starting in the 1960's, several construction projects based on the alkali activation of slag were carried out in the former Soviet Union and China. Some examples include concretes for residential buildings, masonry blocks, irrigation ditches and roads among others (Shi, Krivenko & Della 2006).

The performance of alkali activated slag binders can be considerably affected by mixing proportions, slag fineness, aggregate volume and the type and amount of activating solutions. For this reason, a design of experiments was conducted with the objective of analyzing and understanding the individual and joint effects of the SiO₂/K₂O, H₂O/ K₂O molar ratios of the activating solution, slag/solution and Wollastonite/slag mass ratios as well as the total amount mixed in the setting time and compressive strength of the paste. The setting time was measured using a Vicat needle immediately after mixing while the compressive strength was taken 7 days after curing. An optimal formulation has been proposed considering the results obtained throughout these experiments. This formulation compromises a balance between compressive strength and setting time.

In addition, the linearity of the ratios' effect was investigated. The initial hypothesis was that if the effect of all ratios is linear, then the response values at the center points could be accurately predicted by the response values in the corner points. The replicated center points could also provide a direct estimate of the variation in the response.

II. METHODS

A. Design of Experiments

The design of experiments consisted of 20 runs, where each run was equal to one batch of slag binder, and one batch generated 12 samples. This design is called 2⁵⁻¹ half-fraction factorial with 4 center points. The *half-fraction factorial* design is usually run in early stages of experimentation in order to reduce resources needed in half; 16 out of the 20 suggested points were located on the extremes of the design. These extremes are runs in which each factor is set to its low or high levels. As mentioned before, the remaining 4 runs were in the center of the design, and every factor was set to its middle setting. Table I show the factors with their units, as well as their low, middle and high level values. The high

setting values had to be changed after performing the first 20 runs due to the lack of workability of the paste. For these cases, the mass ratio of Wollastonite/slag was modified from 0.5 to 0.37 and slag/solution from 2 to 1.75.

Table I. Factors and levels tested in the design of experiments. The SiO₂/K₂O and H₂O/K₂O molar ratios correspond to the activating solution. Note that the mass ratios for the high levels were modified from Wollastonite/Slag = 0.5 to 0.37 and Slag/Solution = 2 to 1.75 to improve workability.

Factor	Units	Low	Center	High
SiO ₂ /K ₂ O	mole ratio	1	1.5	2
H ₂ O/K ₂ O	mole ratio	10	15	20
Slag/Solution	mass ratio	1	1.5	2
Wollastonite/Slag	mass ratio	0	0.25	0.5
Total Amount	mass, kg	1	1.5	2

Table I. Factors and levels tested in the design of experiments.

The SiO₂/K₂O and H₂O/K₂O molar ratios correspond to the activating solution. Note that the mass ratios for the high levels were modified from Wollastonite/Slag = 0.5 to 0.37 and Slag/Solution = 2 to 1.75 to improve workability.

B. Materials

St. Mary's Cement Ground Granulated Blast Furnace Slag

Oxide	CaO	SiO ₂	Al ₂ O ₃	MgO	Na ₂ O	K ₂ O	SO ₃
Mass Percent	38.3	37	8	10.5	0.25	0.43	1.7

The activating solution was produced with a 45% KOH solution (Brainerd Chemical Company), distilled water, and silica fume (Aerosil 300). These materials were properly weighted and mixed to achieve the SiO₂/K₂O and H₂O/ K₂O molar ratios previously shown in Table I. The solution was left to mature for 24 hours. Wollastonite (NYAD G, NYCO Minerals) was used as reinforcement in some of the experiments.

C. Procedure

The mixing amounts of GGBFS, activating solution, and Wollastonite for each run were determined by the design of experiments procedure shown in Table I. These materials were mixed in a Hobart mixer until a homogenous paste was observed. The resulting paste was casted in cylindrical molds,

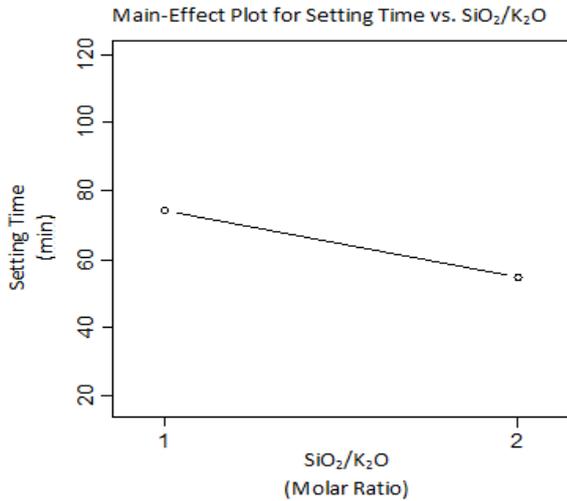

Figure 4. Main-Effect plot for Setting Time vs. SiO₂/K₂O displaying the average over all conditions tested.

Figures 5 and 6 present the interaction between Wollastonite/slag and slag/solution mass ratios and their effect on setting time and compressive strength. It is important to mention that the initial high/high setting level for these two factors did not achieve a workable mixture, for this reason the condition (1.75, 0.37) was used instead. From figure 5, it can be concluded that as the level of Wollastonite/slag and slag/solution increases, the setting time decreases, hence reducing the workability of the paste. On the other hand, in average, increasing the amount of Wollastonite for any ratio of slag/solution increases the compressive strength; this effect is presented in Figure 6.

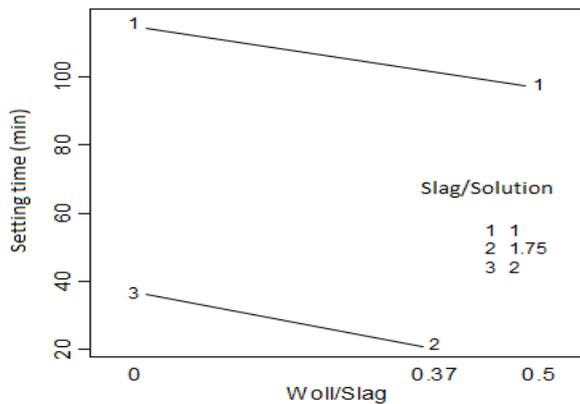

Figure 5. Interaction plot of setting time vs. low, medium and high setting levels of wollastonite/slag and slag/solution mass ratios

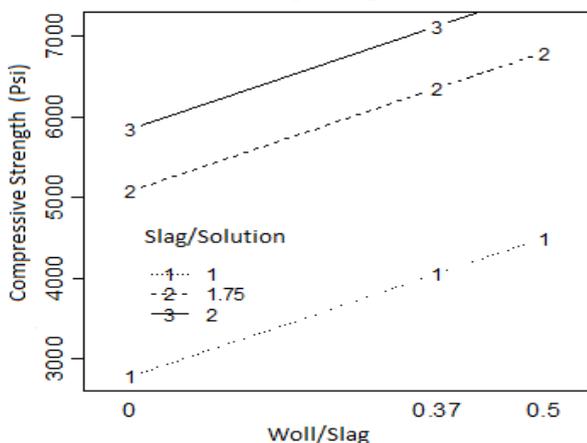

Figure 6. Interaction plot for 7 day compressive strength for low, medium and high levels of Wollastonite/slag and slag/solution ratios.

Figure 7 shows the correlation between compressive strength, slag/solution, and Wollastonite/slag for each solution ratio of the activating solution. The graphs were arranged by solution ratios allowing the comparison of SiO₂/ K₂O from up-down, and H₂O/ K₂O from left-right. For practical purposes, the unmixable samples' compressive strength was assumed to be zero. It was noticed that as the amount of Wollastonite and slag increases, so does the compressive strength. However, once the Wollastonite/slag = 0.5 and slag/solution = 2 the paste become unmixable. Therefore, once the formulation reaches an optimal performance, measured by the highest compressive strength, increasing the ratios of Wollastonite/slag and slag/solution has the opposite effect and the compressive strength declines.

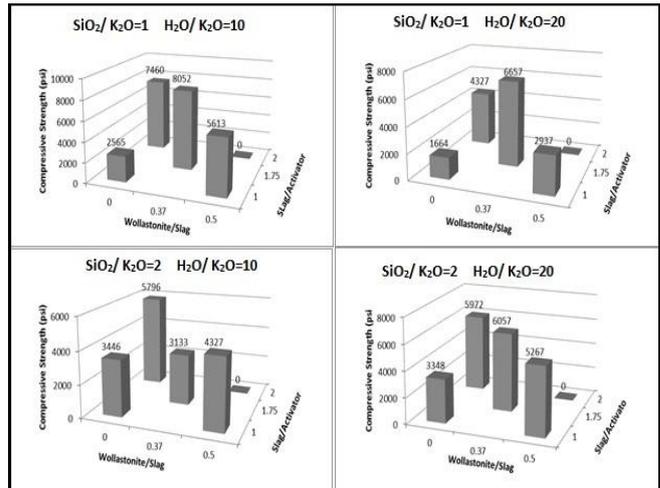

Figure 7. Relationship between compressive strength, wollastonite/slag, and slag/solution for each of the different molar ratios in the activating solution.

IV. CONCLUSIONS

From the 5 regressor variables initially used in the regression model, the total amount mixed showed no significant impact on either of the response variables. It was determined that a high correlation exist between setting time and the slag/solution, SiO₂/K₂O, and Wollastonite/slag ratios. As the slag/solution and Wollastonite/slag mass ratios increase, the setting time decreases. There is a similar trend when increasing SiO₂/K₂O molar ratio in the activating solution.

According to the results from this research, the optimal formulation for alkali-activated slag binders must have a low SiO₂/K₂O molar ratio in the activating solution, with high mass ratios of slag/solution and Wollastonite/slag without passing the binder's workability level. The optimal compressive strength found after 7 days of curing was of 8050 psi (55 MPa) with a setting time of 36 minutes. This compressive strength corresponds to the mix with molar ratios in the activating solution of SiO₂/K₂O=1, H₂O/K₂O=10, mass ratios for slag/solution=1.75 and Wollastonite/slag=0.37 (low/low/high/high combination). Since it was found that H₂O/K₂O has a small effect on compressive strength, it is recommended to further investigate the impact of higher levels of this molar ratio to modify the setting time without affecting the mechanical properties of the binders.

V. ACKNOWLEDGMENT

The authors would like to thank Nyco minerals, Manitou Concrete and McNair Scholars program at RIT for providing financial and in-kind support for this project.
